Abstract

This white paper discusses how VMware's vSphere Storage APIs for Array Integration, also known as VAAI, can be used to offload perform various virtual machine operations on the Dell EMC VMAX® and PowerMax®.

Executive summary

VMware vSphere Storage APIs is a family of APIs used by third-party hardware, software, and storage providers, such as Dell EMC, to develop components that enhance several vSphere features and solutions. This paper focuses on one component of those APIs known as VMware’s Storage APIs for Array Integration (VAAI - also formerly known as vStorage APIs). Dell EMC currently offers four storage integrations as part of VAAI. These integrations are available beginning with Enginuity 5876 2012 Q4 SR (5876.159.102) on the VMAX, 5977 HYPERMAX OS on the VMAX3/VMAX All Flash, and PowerMaxOS 5978 on the PowerMax running with VMware vSphere 6.0\(^1\) and higher. VAAI, by default, provides the ability to offload specific storage operations to the Dell EMC VMAX and PowerMax to increase both overall system performance and efficiency. The four main VMware’s Storage APIs supported by VMAX and PowerMax\(^2\) are:

- **Full Copy\(^3\)**. This feature delivers hardware-accelerated copying of data by performing all duplication and migration operations on the array. Customers can achieve considerably faster data movement via VMware Storage vMotion\(^\circledast\), and virtual machine creation and deployment from templates and virtual machine cloning. Full Copy is also referred to by the SCSI command that is issued for it, XCOPY.

- **Block Zero**. This feature delivers hardware-accelerated zero initialization, greatly reducing common input/output tasks such as creating new virtual machines. This feature is especially beneficial when creating fault-tolerant (FT)-enabled virtual machines or when performing routine application-level Block Zeroing.

- **Hardware-assisted locking**. This feature delivers improved locking controls on Virtual Machine File System (VMFS), allowing far more virtual machines per datastore and shortened simultaneous block virtual machine boot times. This improves performance of common tasks such as virtual machine migration, powering many virtual machines on or off and creating a virtual machine from a template. This feature will be discussed only briefly in this paper.

- **UNMAP**. This feature enables the reclamation of blocks of thin-provisioned LUNs by informing the array that specific blocks are obsolete. Until vSphere 6.5, UNMAP does not occur automatically on datastores - it is performed at the VMFS level as a manual process. In vSphere 6.0 Guest OS UNMAP was introduced which reclaims storage within a thin vmdk, and beginning in vSphere 6.5 automated UNMAP at the VMFS level is available.

In addition to the four main APIs, VAAI includes an API for Thin Provisioning. Thin Provisioning is enabled by default in Enginuity 5875 and higher (includes all HYPERMAX and PowerMaxOS versions). Thin Provisioning permits a couple

---

1 VMware ended general support for vSphere 5.5 in September 2018. Therefore, only vSphere 6.0 and higher will be covered in this white paper.
2 This whitepaper will sometimes use the generic term VMAX when referring to VMAX3, VMAX All Flash, and PowerMax arrays. When necessary the individual array type will be called out.
3 Full Copy is supported on the VMAX3 platform beginning with the 5977 2014 Q4 SR (5977.498.472) release.
capabilities. First, the API allows ESXi to tell the array when space can be reclaimed on a thin provisioned LUN. This is essential for UNMAP. Second, the API supports out of space errors. This means the array can notify ESXi when it is running out of space. The out of space errors capability is sometimes referred to as “Stun & Resume” because when a VM runs out of space on the array, rather than crashing, it will enter a “stunned” state until the user increases space (or powers off the VM) on the array allowing the VM to “resume”.

To determine whether a device supports the Thin Provisioning API, query it using esxcli:

```
esxcli storage core device list
```

One of the columns is called “Thin Provisioning Status”. When the API is supported, this column will return “yes”, when not supported the status will be either “no” or “unknown”. In the screen below, Figure 1, a VMAX supported device is shown on the left, while an unsupported, local device is on the right.

![Thin Provisioning Status](image)

Figure 1. Thin Provisioning Status

When running the supported versions of Enginuity/HYPERMAX OS/PowerMaxOS and vSphere, VAAI functionality is enabled by default on any VMAX or PowerMax array.4

This paper will discuss the operation of and best use cases for utilizing VAAI features with the VMAX. In doing so, it will demonstrate how to maximize efficiency and increase the effectiveness of a VMware vSphere 6.x environment deployed on a VMAX.

This paper covers Enginuity 5875/HYPERMAX OS 5977 and later and through the PowerMaxOS 5978.479.479 release.

---

4 Prior to vSphere 6.5, UNMAP will require running vmkfstools or esxcli storage vmfs unmap manually, depending on the ESXi version.
Audience
This technical white paper is intended for VMware administrators and storage administrators responsible for deploying VMware vSphere and the included VAAI features.

VAAI primitives
Storage APIs for Array Integration is an API for storage partners to leverage that permits certain functions to be delegated to the storage array, thus greatly enhancing the performance of those functions. This API is fully supported by the VMAX and PowerMax running the appropriate software. This array offload capability supports four primitives: hardware-accelerated Full Copy, hardware-accelerated Block Zero, hardware-assisted locking, and UNMAP.

It is important to note that the primitives will not cause failures in the vSphere environment if conditions prevent their use. In such cases, VMware simply reverts back to the default software behavior. For example, if the Full Copy primitive is enabled and a user attempts to clone a VM to a local datastore which does not support hardware acceleration, VMware will revert to the default software copy. The primitives may also be enabled or disabled even in the middle of operations that are utilizing them. At the point of change, VMware will immediately begin using the opposite capability of what was being used – software to offload or offload to software – and finish the task with that methodology (assuming no further change is made).

Hardware-accelerated Full Copy or XCOPY
The time it takes to deploy or migrate a virtual machine will be greatly reduced by use of the Full Copy primitive, as the process is entirely executed on the storage array and not on the ESXi server. This greatly reduces overall traffic on the ESXi server. In addition to deploying new virtual machines from a template or through cloning, Full Copy is also utilized when doing a Storage vMotion. When a virtual machine is migrated between datastores on the same array the hot copy is performed entirely on the array.

Full Copy is implemented as an asynchronous process on the VMAX. When using the VMAX, the host simply passes information to the array about what data to copy or move and to what location it should be moved or copied. The progress of this transfer of information is what is seen in the vSphere Client. When the vCenter reports that the clone or Storage vMotion task is complete, it means the VMAX has received all the information it needs to perform the task. The array, using the same mechanism as the Dell EMC TimeFinder local replication software, then completes the transfer of data asynchronously. The end-user is completely unaware of this since the virtual machine is available during the Storage vMotion, or in the case of a clone immediately after the vCenter task is complete.

In order to ensure that the Full Copy process does not over-utilize array resources, thereby impacting critical operations, there is an upper ceiling that can be reached if
many clones and/or Storage vMotions are performed at once. On the VMAX3/VMAX All Flash/PowerMax in particular, reaching these limits are very unlikely; however if it does occur, vSphere seamlessly switches to software copy in mid-operation. VMware vSphere will retry the XCOPY command after a short time, at which point if resources are available, the array copy will resume. Note that a clone or Storage vMotion can switch back and forth between software and hardware copies without any user intervention, and in fact without the end-user knowing. If the user wishes to monitor such activity, the section Monitoring VAAI operations with ESXTOP in this paper provides detail.

Not only does Full Copy save time, but it also saves server CPU cycles, memory, IP and SAN network bandwidth, and storage front-end controller I/O. This is due to the fact that the host is relieved of the normal function it would serve of having to read the data from the array and then write the data back down to the array. That activity requires CPU cycles and memory as well as significant network bandwidth. Figure 2 provides a graphical representation of Full Copy.

VMAX, not the host, moves the data from the Source to the Target

Figure 2. Hardware-accelerated Full Copy

**Hardware-accelerated Block Zero**

Using software to zero out a virtual disk is a slow and inefficient process. By passing off this task to the array, the typical back and forth from host to array is avoided and the full capability of the VMAX can be utilized to accomplish the zeroing.
A typical use case for Block Zeroing is when creating virtual disks that are eagerzeroedthick (EZT) in format. Without the Block Zeroing primitive, the ESXi server must complete all the zero writes of the entire disk before it reports back that the disk zeroing is complete. For a very large disk this is time-consuming. When employing the Block Zeroing primitive as in Figure 3, (also referred to as “write same” since it uses the WRITE SAME SCSI operation (0x93) to achieve its task) the disk array returns the cursor to the requesting service as though the process of writing the zeros has been completed. It then finishes the job of zeroing out those blocks asynchronously, without the need to hold the cursor until the job is done, as is the case with software zeroing.

Block Zero is also initiated with “zeroedthick” or “thin” virtual disks when a guest operating system writes to a previously unallocated portion of the disk. When a new write comes through, ESXi issues write same to the block(s) and then executes the write. The Block Zero operation is only performed once per block upon a first write, subsequent writes to the same block are not preceded by a Block Zero operation. Block Zero is also leveraged during an initial format of a VMFS volume to reserve space for VMFS metadata. Note that only a small portion of the device when formatted as a VMFS volume is actually reserved.

This primitive has a profound effect when deploying "eagerzeroedthick" virtual disks or writing to unallocated sectors of a “zeroedthick” or “thin” virtual disk. When enabled, the VMAX will not actually write the zeros to disk but instead simply allocate the relevant tracks on the thin pool (if not already allocated) and then set the Never Written By Host flag on them. Block Zero operations therefore result in allocated, but not written to, tracks. Tracks such as these will always return zeros to a host read and will be skipped in the case of a TimeFinder or SRDF copy.

On the VMAX3/VMAX All Flash/PowerMax, however, the architecture is different and no space is actually reserved. This is because the VMAX3/VMAX All Flash/PowerMax can be thought of as a single pool of storage, since new extents can be allocated from any thin pool on the array. Therefore, the only way that a thin device can run out of space is if the entire SRP runs out of space. It was deemed unnecessary, therefore, to reserve space on the VMAX3/VMAX All Flash/PowerMax when using Block Zero. Note, however, that because of the architecture of the VMAX3/VMAX All Flash/PowerMax there is no performance impact even though the space is not pre-allocated.
Figure 3. Hardware-accelerated Block Zero

Hardware-assisted locking

As a clustered shared-storage manager, VMware’s Virtual Machine File System (VMFS) needs to coordinate the access of multiple ESXi server hosts to parts of that shared storage. VMFS allocates part of the storage available to it for data describing virtual machines and their configurations, as well as the virtual disks that they access. Within a cluster of ESXi servers the virtual machines contained in the VMFS datastore can be loaded and run on any of the ESXi instances. They can also be moved between instances for load balancing and high availability.

VMware has implemented locking structures within the VMFS datastores that are used to prevent any virtual machine from being run on, or modified by, more than one ESXi host at a time. This locking metadata update operation is used by VMware whenever a virtual machine’s state is being changed. This may be a result of the virtual machine being powered on or off, having its configuration modified, or being migrated from one ESXi server host to another with vMotion or Dynamic Resource Scheduling. The initial implementation of mutual exclusion for updates to these locking structures was built using SCSI RESERVE and RELEASE commands. This protocol claims sole access to an entire logical unit for the reserving host until it issues a release. Under the protection of a SCSI RESERVE, a server node could update metadata records on the device without the risk of interference from any other host attempting to update the same records. This approach, which is shown in Figure 4, has significant impact on overall cluster performance since access to the device by other hosts is prevented while SCSI RESERVE is in effect. As ESXi clusters have grown in size, as well as in their frequency of modifications to the virtual machines they are
running, the performance degradation from the use of SCSI RESERVE and RELEASE commands has become unacceptable.

![Image of traditional VMFS locking before hardware-assisted locking]

**Figure 4. Traditional VMFS locking before hardware-assisted locking**

This led to the development of the third primitive for VAAI, hardware-assisted locking or ATS. This primitive provides a more granular means of protecting the VMFS metadata than SCSI reservations. Hardware-assisted locking leverages a storage array atomic test and set capability to enable a fine-grained block-level locking mechanism as shown in Figure 5. Firstly, hardware-assisted locking replaces the sequence of RESERVE, READ, WRITE, and RELEASE SCSI commands. It does this with a single SCSI request for an atomic read-modify-write operation conditional on the presumed availability of the target lock. Secondly, this new request only requires exclusivity on the targeted locked block, rather than on the entire VMFS volume containing the lock.
Figure 5. VMFS locking with hardware-assisted locking

Although the non-hardware assisted SCSI reservation locking mechanism does not often result in performance degradation, the use of hardware-assisted locking provides a much more efficient means to avoid retries for getting a lock when many ESXi servers are sharing the same datastore. Hardware-assisted locking enables the offloading of the lock mechanism to the array and then the array does the locking at a very granular level. This permits significant scalability in a VMware cluster sharing a datastore without compromising the integrity of the VMFS shared storage-pool metadata.

ATS heartbeat

One of the types of locks that VMware performs is called the heartbeat. The heartbeat is used to synchronize operations between multiple hosts as well as check on the vitality of the host. Before ESXi 5.5 U2, VMware used SCSI reads and writes to implement the heartbeat, even on storage arrays that supported VAAI (ATS). Beginning with ESXi 5.5 U2, however, VMware defaults to using ATS on supported arrays, offloading the heartbeat management. The change in behavior means there is a significant increase in the ATS traffic to the storage array, in this case the VMAX. Under certain load conditions, ATS may fail with a false ATS miscompare.\(^5\) Upon failure ESXi will then re-verify its access to the datastore which will lead to error messages in the vSphere Client similar to: Lost access to datastore. An ATS miscompare message can also

\(^5\) VMware KB article 2113956. Although the KB refers to an IBM storage system, the error can occur on any storage platform.
be found in the /var/log/vmkernel.log file. In the unlikely event that this error is recurring in the environment, VMware and Dell EMC recommend disabling ATS for the heartbeat mechanism only, which means ESXi will revert to the non-ATS functionality, or SCSI reads and writes. Like almost all VAAI functions, disabling the ATS heartbeat is executed online.

To view the current setting (Int Value) for the ATS heartbeat, execute the command in Figure 6:

```
esxcli system settings advanced list -o /VMFS3/UseATSForHBOnVMFS5
```

![Figure 6. ATS heartbeat setting](image)

As noted in Figure 6, the default value is on (1). In order to disable it, run the following command on each host that accesses the datastore in question. Note it will not return a response:

```
esxcli system settings advanced set -i 0 -o /VMFS3/UseATSForHBOnVMFS5
```

The execution and result is shown in Figure 7.

![Figure 7. Disabling ATS heartbeat setting](image)
Disabling the ATS heartbeat does not impact any other locking functions that are also handled by the VAAI ATS primitive. Its sole impact is on the creation or updating of the VMFS heartbeat. VMware indicates there should be no performance impact by disabling the ATS heartbeat. It is critical to understand that the ATS heartbeat is a subset of functionality of ATS and that the ATS primitive (VMFS3.HardwareAcceleratedLocking) itself should never be disabled.

vSphere 6.5

Beginning in vSphere 6.5, VMware has changed how it reacts to an ATS miscompare. Instead of aborting the IOs and assuming the ATS miscompare is legitimate, VMware will retry the read to determine if the miscompare is accurate. If it is accurate, the previous process applies; however, if the on-disk heartbeat data has not changed, meaning the miscompare was false, VMware will retry the heartbeat after some milliseconds.

VMware has also corrected another miscompare event where it was not able to determine if a heartbeat made it to disk. VMware now uses an earlier heartbeat record to determine the validity of the ATS miscompare and then proceeds appropriately. The new vSphere 6.5 functionality works in both VMFS 5 and VMFS 6 and negates the need to ever disable the ATS heartbeat. If upgrading from ESXi 5.5 U2 or higher where the heartbeat was disabled, be sure to re-enable when reaching ESXi 6.5.

UNMAP

The purpose behind UNMAP is the reclamation of space in the thin pool on the array. UNMAP can be utilized in two different scenarios. The first is to free space in a VMFS datastore – manually or automatically. The second is to free space in a thin vmdk that is part of a Guest OS in a VM. This is known as Guest OS, or in-guest UNMAP, and was introduced in vSphere 6.0 with Windows 2012 R2 and expanded to Linux in vSphere 6.5. It supports both VMFS and vVol datastores.

Datastore

As virtual machines are created and grow, then are moved or deleted, space is stranded in the thin pool because the array does not know that the blocks where the data once resided is no longer needed. Prior to the integration of this new Storage API in vSphere and in the VMAX, reclamation of space required zeroing out the unused data in the pool and then running a zero reclaim process on the array. With UNMAP support, vSphere tells the VMAX what blocks can be unmapped or reclaimed. If those blocks span a complete extent or extents, they are deallocated and returned to the thin pool for reuse. If the range covers only some tracks in an extent, those tracks are marked Never Written By Host (NWBH) on the VMAX but the extent cannot be deallocated. This is still beneficial, however, as those tracks do not have to be retrieved from disk should a read request be performed. Instead, the VMAX array sees

---

6 UNMAP in this scenario does not support vVol datastores as a vVol datastore is a logical construct and is comprised of many devices, not a single device like a VMFS datastore. It is not needed, however, as when an individual vmdk is removed, the vVol on the array is also deleted, thus freeing the space.
the NWBH flag and immediately returns all zeros. The VMAX3/VMAX All Flash/PowerMax performs a similar process.

VMware will, of course, reuse existing space in the datastore even if the data has not been reclaimed on the array; however, it may not be able to use all of the space for a variety of reasons. In addition, by reclaiming the space in the thin pool it becomes available to any device in the pool, not just the one backing the datastore. The use of the SCSI command UNMAP, whether issued manually or automatically, is the only way to guarantee that the full amount of space is reclaimed for the datastore.

**Guest OS**

Guest OS or in-guest UNMAP was introduced in vSphere 6.0. In the initial release it supported Windows 2012 R2 and higher but not Linux. In vSphere 6.5 SPC-4 support was added which enables Guest OS UNMAP for Linux VMs. There are several prerequisites that must be met to take advantage of Guest OS UNMAP. There are some differences between the two vSphere versions that should be noted. They are covered in the next two sections.

**vSphere 6.0 and Windows 2012 R2+**

To enable Guest OS UNMAP in vSphere 6.0, the prerequisites are as follows:

- ESXi 6.0+
- Thin virtual disk (vmdk)
- VM hardware version 11+
- 64k allocation unit (recommended) for NTFS
- The advanced parameter EnableBlockDelete must be set to 1 if using VMFS (vVols do not require the parameter). It is off by default.
  
o esxcli system settings advanced set --int-value 1 --option /VMFS3/EnableBlockDelete

An important note is that change block tracking (CBT) is not supported with Guest OS UNMAP in vSphere 6.0 but is supported in vSphere 6.5.

**vSphere 6.5+ and Linux**

To enable Guest OS UNMAP in vSphere 6.5+, the prerequisites are as follows:

- ESXi 6.5+
- Thin virtual disk (vmdk)
- VM hardware version 13+
- A Linux OS and file system that supports UNMAP

---

7 A VMware bug exists which can limit the amount of space reclaimed if the allocation unit is not 64k. If using Guest OS UNMAP, applying the patch which resolves the bug is recommended. See VMware KB 2148987 for detail.
• The advanced parameter EnableBlockDelete must be set to 1 if using VMFS 5 (vVols do not require the parameter). It is off by default.

  o esxcli system settings advanced set --int-value 1
     --option /VMFS3/EnableBlockDelete

While Windows automatically issues UNMAP, Linux does not do so by default. Though sg_unmap and fstrim can be issued manually to free space, a simple parameter is available on file systems to reclaim space automatically. When mounting the file system (e.g. ext4), use the discard option and all deleted files will cause UNMAP to be issued. Here is an example.

  mount /dev/sdb1 /u02 -o discard

VAAI and Dell EMC Enginuity/HyperMAX OS/PowerMaxOS version support

Dell EMC’s implementation of VAAI is done within the Enginuity, HYPERMAX OS, and PowerMaxOS software. As with any software, bugs are an inevitable byproduct. While Dell EMC makes every effort to test each use case for VAAI, it is impossible to mimic every customer environment and every type of use of the VAAI primitives. To limit any detrimental impact our customers might experience with VAAI, the following table, Table 1, is provided. It includes all current releases and any E Packs that must be applied at that level, beginning with the recommended base level of 5875 to the current 5978 release. Using this table will ensure that a customer's array software release is at the proper level for VAAI interaction. It is essential to review both the Important Notes column and any footnotes.

In August 2016, VMware ended general support for vSphere 5.0 and 5.1. More recently, support for vSphere 5.5 ended in September 2018. Therefore vSphere 6.0 will be the minimum release listed in the table below.

</table>

---

8 A bug in vsphere 6.5 when using VMFS 6 prevents manual UNMAP from functioning properly. This is resolved in vsphere 6.5 U2 and therefore is the recommended patch level for vsphere 6.5.

9 A bug in vsphere 6.7 causes VMware to send UNMAP commands at a rate faster than the selected priority or fixed value. This impacts the default priority (low, 25 MB/s) significantly. A patch is available to resolve this bug and customers are strongly advised to apply it to each ESXi host. The relevant bug PR is 2411494.

10 A rare XCOPY bug exists that can cause VMFS corruption (PowerMaxOS only) which is resolved through a VMware and Dell EMC patch. The relevant VMware builds which contain the patch are 14990892 for 6.5 and 15018017 for 6.7. The Dell EMC patch will be officially released in Feb 2020 and is required to prevent the bug (the VMware patch is strongly recommended but not required). More information is available in DTA 537000. Dell EMC recommends applying the VMware patches in anticipation of the release of the Dell EMC patch. The patches, however, can be applied in any order.

</table>

Be aware that this table only displays information related to using vSphere with VAAI and Enginuity/HYPERMAX OS/PowerMaxOS. It is not making any statements about general vSphere support with Enginuity/HYPERMAX OS/PowerMaxOS. For general support information consult E-Lab Navigator. It may also not contain every release available.

**Compression/Deduplication**

Starting with HYPERMAX OS release 5977 2016 Q3 SR, Dell EMC offers compression on VMAX All Flash arrays. Starting with PowerMaxOS 5978 on PowerMax, both compression and deduplication are supported. Compression and deduplication are not available on VMAX3 arrays and deduplication is not available on VMAX All Flash arrays. The VAAI primitives are fully supported with compression and deduplication and no user intervention is required when these features are employed.

**Host I/O Limits**

Dell EMC provides support for the setting of Host I/O Limits. This feature allows users to place limits on the front-end bandwidth and IOPS consumed by applications on VMAX and PowerMax systems.

Limits are set at the storage group level. As users build masking views with these storage groups, limits for maximum front-end IOPS or MBs/s are evenly distributed across the directors within the associated masking view. The bandwidth and IOPS are...
monitored by the array to ensure that they do not exceed the user-specified maximum, throttling when necessary.

VAAI interacts with Host I/O Limits in that the commands issued by VMware to the array count toward either IOPS or MBs/s. From an IOPS perspective, these commands are counted as individual IOs and register as regular metrics based on front-end activity. From a bandwidth perspective, UNMAP and Full Copy commands are counted as individual IOs of modest size since the code doesn’t know the actual extent sizes. But the address ranges that VMware passes with the Block Zero commands count against the Host I/O MBs/s limit. This activity will show up in the Host IO Limit MBs/sec metric, while not showing up in the regular Host MBs/sec metric.

In the following example, a 50 MB/s Host I/O Limit was set on a storage group with a single 500 GB device. A 250 GB eagerzeroedthick disk was created on the device. Figure 8 shows that the Write Same commands are being counted against the limit (yellow line), but the array is not registering it as regular IO (blue line). Note also the time it takes to create the vmdk - more than 1 hour. The normal creation time is about 30 seconds. This example of course is exaggerated by using a very small size for the limit yet demonstrates how VAAI and Host I/O Limits interact.

![Figure 8. Host IO Limits with VAAI](image)

**Viewing VAAI support**

Through the CLI or within the vSphere Client, one can see whether a particular device or datastore supports hardware acceleration or VAAI. From the CLI, using the Network Addressing Authority (NAA) identifier, the status for each VAAI primitive can be seen as in Figure 9.
Figure 9. Viewing VAAI primitive support through the CLI with and without UNMAP support (Delete Status)

It is important to remember that querying the device provides the status from the array’s perspective and not vSphere’s. This means that if a primitive is disabled within ESXi, the query will still show the primitives as supported by the array. As it is possible to disable primitives on the array itself, however, the query could return an unsupported value for one of those primitives. Figure 10 shows when both UNMAP and XCOPY are disabled at the array level. Note that only Delete Status is reported as being unsupported and not Clone Status.
If using eNAS and thus NFS with VMAX3/VMAX All Flash/PowerMax (see section eNAS and VAAI), to view VAAI support run the vmkfstools command shown in Figure 11.

In the vSphere Client GUI (HTML 5) to view VAAI support, first navigate to the chosen datastore in the left-hand panel. Then select Configure → Hardware Acceleration. The Hardware Acceleration column indicates the support status of the primitives for the device or datastore. There are three possible values that can populate this column: “Supported”, “Not supported”, or “Unknown”. This column is shown in Figure 12.

---

12 A particular device or datastore may be labeled as “Unknown” until it is successfully queried.
Figure 12. Viewing VAAI support in the vSphere Client

Note that this column, unlike the CLI, does not provide any detail about the individual primitives. For example, if hardware-accelerated locking is supported but not UNMAP, this column will still show “Supported”.

The Hardware Acceleration column does not indicate whether the primitives are enabled or disabled, only whether they are supported.

VAAI Statistics

Prior to PowerMaxOS 5978.444.444 there is no user interface to view VAAI primitive activity on the array. For Full Copy, however, if the Solutions Enabler command `symdev show` is run against the source or target device involved in a hardware-accelerated operation, the parameter “Extent Based Clone” will either display “Source” or “Target”.

Beginning with PowerMaxOS 5978.444.444, Unisphere for PowerMax includes the following VAAI statistics at the thin device\(^\text{13}\) and storage group level:

- VAAI Total Command Count
- VAAI Total Time
- VAAI Unmap Command Count
- VAAI Unmap KB
- VAAI Unmap MB
- VAAI Write Same Command Count
- VAAI Write Same KB

\(^{13}\) These metrics are not available for vVols.
- VAAI Write Same MB
- VAAI XCopy Command Count
- VAAI XCopy KB
- VAAI XCopy MB

In the Performance tab of Unisphere, you can find the VAAI metrics under “All”. This is displayed in Figure 13. The only VAAI metric that is a KPI is VAAI Total Command Count.

The statistics available in Unisphere do not directly correlate with what VMware records for commands in esxtop so it is not beneficial to compare them; however, the Unisphere stats provide information not available in esxtop such as the amount of storage that was reclaimed during a recent auto UNMAP process.
UNMAP Example

In this example, two VMs were removed from a datastore with auto UNMAP enabled. VMware issued 3024 UNMAP commands, however the array only required 10 commands to unmap the space on the array as seen in Figure 14. Those 10 commands reclaimed about 215 MB of space.

Figure 14. UNMAP statistics example

XCOPY Example

In the following example, a virtual machine was cloned within the same datastore which will engage XCOPY. Two clones were executed, the first using the default transfer size of 4 MB, and the second using the maximum transfer size (without a claim rule) of 16 MB. Note the values in Figure 15.
Figure 15. XCOPY transfer size

Figure 16 is a screenshot of the results of the two clones. Note the first run in the left of each graph where there were 12 XCOPY commands issued for a total of ~48 MB. When the transfer size was changed to 16 MB and the clone re-run, notice that the command count was reduced to 3 because the copy size had been quadrupled. The size of the actual copied data, however, does not change. Remember, though, that the max transfer size is just that, a max, and that depending on the data being copied there may not always be perfect ratio between the original copy count and the one done after changing the transfer size.
Figure 16. XCOPY statistics example

The new statistics are obviously most useful to tell when a device or devices in a storage group are involved in VAAI activity. Knowing this information can perhaps help diagnose performance issues or in determining if even VAAI commands are being issued.

Enabling the Storage APIs for Array Integration\textsuperscript{14}

Full Copy, Block Zero, and Hardware-assisted locking

The VAAI primitives are enabled by default on both the VMAX using ESXi servers (properly licensed\textsuperscript{15}) and should not require any user intervention.\textsuperscript{4} Three of the primitives, however, can be disabled through the ESXi server if desired, either through the CLI or GUI. Using the vSphere Web Client/vSphere Client\textsuperscript{16}, Full Copy and Block Zero can be disabled or enabled independently by altering the respective settings, \textit{DataMover.HardwareAcceleratedMove} and \textit{DataMover.HardwareAcceleratedInit}, in the ESXi server advanced settings under DataMover as shown in Figure 17. Under normal circumstances, these settings should not be altered.

\textsuperscript{14} This section on enabling and disabling VAAI does not apply to VAAI with NFS. Once the EMC NAS plug-in is installed, VAAI for NFS is enabled and cannot be disabled using any of the methods described in this paper.

\textsuperscript{15} Refer to VMware documentation for required licensing to enable VAAI features.

\textsuperscript{16} Though the Thick Client is deprecated in later releases, it is still possible to use it even with vSphere 6.5 to set these values.
Figure 17. Enabling VAAI in the vSphere Web Client

The vSphere Client is shown in Figure 18.
Disabling or enabling the primitives is a dynamic process on the ESXi server and does not require the ESXi server to be in maintenance mode, nor does it necessitate a reboot of the server.

Automated UNMAP

Beginning with vSphere 6.5, VMware offers automated UNMAP capability at the VMFS 6 datastore level (VMFS 5 is not supported). The automation is enabled by a background process (UNMAP crawler) which keeps track of which LBAs that can be unmapped and then issues those UNMAPs at various intervals. It is an asynchronous process. VMware estimates that if there is dead space in a datastore, automated UNMAP should reclaim it in under 12 hours.

UNMAP is enabled by default when a VMFS 6 datastore is created through the vSphere Client wizard. There are two parameters available, one of which can be modified: Space Reclamation Granularity and Space Reclamation Priority. The first parameter, Space Reclamation Granularity, designates at what size VMware will reclaim storage. It cannot be modified from the 1 MB value. The second parameter, Space Reclamation Priority, dictates how aggressive the UNMAP background process will be when reclaiming storage. This parameter only has 2 values: None (off), and Low. It is set to Low by default. These parameters are seen in Figure 19.
If it becomes necessary to either enable or disable UNMAP on a VMFS 6 datastore after creation, the setting can be modified through the vSphere Web Client or CLI. Within the datastore view in the Client, navigate to the Configure tab and the General sub-tab. On this page, find a section on Space Reclamation where the Edit button can be used to make the desired change as in Figure 20.
Figure 20. Modifying automated UNMAP on a VMFS 6 datastore

Changing the parameter is also possible through CLI, demonstrated in Figure 21.

Figure 21. Modifying automated UNMAP through CLI
Though vSphere 6.5 offers automated UNMAP, manual UNMAP using `esxcli` is still supported and can be run on a datastore whether or not it is configured with automated UNMAP. See the section ESXi 6.x for more detail.

**vSphere 6.7**

Beginning with vSphere 6.7, VMware offers the ability to not only change the reclamation priority that is used for UNMAP, but also change the method from priority to a fixed of bandwidth if desired. In addition, the behavior of the priority method changes from vSphere 6.5. Unlike vSphere 6.5, the task is not one initiated in the background that takes place over many hours. In vSphere 6.7 when space is available to UNMAP, VMware will immediate issue the commands at the specified priority. VMware will be able to reclaim the space based solely on the set priority or fixed value.

As explained above, prior to vSphere 6.7 automated UNMAP was either on, which meant low priority, or off. Now priority can be changed to medium or high also, each with their own bandwidth. Medium will translate into 75 MB/s while high will be 256 MB/s (despite the bandwidth indicating 0 MB/s). To change the priority, however, only the CLI is offered.

By default, the “Low” priority setting shown in Figure 19 translates into reclaiming at a rate of 25 MB/s. To change it to medium priority, issue the following command seen in Figure 22:

```
esxcli storage vmfs reclaim config set --volume-label RECLAIM_TEST_6A --reclaim-priority medium
```

![Figure 22. Modifying reclaim priority](image)

To take advantage of the power of all flash storage arrays, VMware also offers the ability to set a fixed rate of bandwidth. The user can set the value anywhere from 100
MB/s to a maximum of 2000 MB/s in multiples of 100. This capability, unlike priority, is offered in the GUI, but only in the HTML 5 client. In the following example in Figure 23, the reclaim method is changed to “fixed” at a 1000 MB/s bandwidth. In this interface it is clear that the priority cannot be changed as previously mentioned.

Figure 23. Modifying reclaim method to fixed

The CLI can also be used for the fixed method. For example, to change the reclaim rate to 200 MB/s on the datastore “RECLAIM_TEST_6A” issue the following:
esxcli storage vmfs reclaim config set –volume-label RECLAIM_TEST_6A –reclaim-method fixed –b 200

Here is the actual output in Figure 24, along with the `config get` command which retrieves the current value.

![PuTTY output showing esxcli storage vmfs reclaim config set command](image.png)

**Figure 24. Changing reclaim priority in vSphere 6.7**

VMware has indicated that they do not advise changing the reclaim granularity.

While an active UNMAP operation is underway, changing the bandwidth value will take longer than normal to complete.

One may notice that in Figure 22, the reclaim bandwidth shows as 0 MB/s, despite knowing the actual value is 75 MB/s. VMware will not show the correct value, however, unless the reclaim method is first set to fixed, then changed back to priority as in Figure 25.
Dell EMC conducted numerous tests on the new UNMAP capabilities in vSphere 6.7, but found little difference in how quickly data is reclaimed on the array. This is consistent with manual UNMAP block options. For example, in Figure 26 there are two reclaim tasks shown. Each one is to unmap 100 GB of storage from the datastore RECLAIM_TEST_6A. The first line is using a fixed method at 1000 MB/s. The second is a priority method at medium (75 MB/s). Each reclaim took the same amount of time and VMware performed the same UNMAP commands.

Figure 25. Showing the actual reclaim bandwidth of medium priority

**Recommendations**

Dell EMC conducted numerous tests on the new UNMAP capabilities in vSphere 6.7, but found little difference in how quickly data is reclaimed on the array. This is consistent with manual UNMAP block options. For example, in Figure 26 there are two reclaim tasks shown. Each one is to unmap 100 GB of storage from the datastore RECLAIM_TEST_6A. The first line is using a fixed method at 1000 MB/s. The second is a priority method at medium (75 MB/s). Each reclaim took the same amount of time and VMware performed the same UNMAP commands.
Figure 26. UNMAP IOPs and size

Because this is only an example and data will be stored in different extent sizes depending on many factors, it is possible larger fixed values will perform better than the priority method, despite these findings; however, based on Dell EMC testing, the recommendation is to continue to use the priority method. By default, VMware keeps the UNMAP rate set to low priority to minimize the impact on VM IO, without regard to the type of storage backing the datastores, and this seems like a prudent strategy. Dell EMC recommends, therefore, to use the default priority method for each of the VMAX or PowerMax datastores.

Automatic UNMAP support for SESparse in vSphere 6.7

In vSphere 6.7, on VM’s with a SESparse snapshot (SESparse is the default snapshot format on VMFS 6), the space reclaimation is now automatic. Note that automatic UNMAP for SESparse will not be triggered until 2 GB of cleared space is achieved.

Full Copy Tuning

By default, when the Full Copy primitive is supported, VMware informs the storage array to copy data in 4 MB chunks. For ESXi hosts that utilize more than VMAX arrays, the default value should not be altered. However, in all-VMAX or a combination of VMAX and VNX environments for vSphere 5.x – 6.x, customers are advised to take advantage of VMware’s ability to send larger chunks to the array for copy. In vSphere 6.x there is a more advanced capability that can be used in all-VMAX environments to increase the extent size even higher. The following two sections outline how to make these changes in the different vSphere environments.
vSphere 6.x

In vSphere 6.x the default copy size can be incremented to a maximum value of 16 MB and should be set at that value for all VMAX/VNX environments to take advantage of the array’s ability to move larger chunks of storage at once.

The following commands show how to query the current copy (or transfer) size and then how to alter it.

```
# esxcfg-advcfg -g /DataMover/MaxHWTransferSize
Value of MaxHWTransferSize is 4096

# esxcfg-advcfg -s 16384 /DataMover/MaxHWTransferSize
Value of MaxHWTransferSize is 16384
```

Note that this change is per ESXi server and can only be done through the CLI (no GUI interface) as in Figure 27:

![Figure 27. Changing the default copy size for Full Copy on the ESXi host](image)

Alternatively, vSphere PowerCLI can be used at the vCenter level to change the parameter on all hosts as in Figure 28.
In vSphere 6.x, the previous outlined mechanism will still work; however, VMware has enabled a different methodology by which the extent size can be increased – claim rules. These claim rules will take precedence over the MaxHWTransferSize and can be utilized with VMAX, VMAX3/VMAX All Flash and PowerMax.

Claim rules have always been used to implement VAAI for VMAX (Figure 7). VAAI is a plug-in claim rule that says if a device is from a particular vendor, in this case a Dell EMC VMAX device, it should go through the VAAI filter. In other words, if VAAI can be used it will be used (various situations exists – detailed in this paper – where primitives like XCOPY will not be used). Each block storage device managed by a VAAI plug-in needs two claim rules, one that specifies the hardware acceleration filter and another that specifies the hardware acceleration plug-in for the device. These claim rules are where the change has been made (in addition to the code). What VMware has done is to add 3 new columns to the storage core claim rules to control the new behavior. They are:

- XCOPY Use Array Reported Values
- XCOPY Use Multiple Segments
- XCOPY Max Transfer Size

Figure 29 shows the original output from vSphere 5.x and Figure 30 shows the output from vSphere 6.x with the new columns and their default values.
By altering the rules and changing these 3 new settings, one can adjust the max transfer size up to a maximum of 240 MB. Though the columns show in both the Filter and VAAI claim rule classes, only the VAAI class needs to be changed. The new required settings are:

- **XCOPY Use Array Reported Values** = true
- **XCOPY Use Multiple Segments** = true
- **XCOPY Max Transfer Size** = 240

It is not sufficient to simply change the transfer size because VMware requires that the array reported values is set to true if the transfer size is set. When use array reported values is set it means that VMware will query the array to get the largest transfer size if the max transfer size is not set or if there is a problem with the value. Unfortunately the VMAX advertises a value higher than 240 MB so in the case of an issue with the transfer size VMware will default to the previous value set for
MaxHWTransferSize; therefore it is important to set that to 16 MB. In addition, for the VMAX to accept up to 240 MB, multiple segments must be enabled since a single segment is limited to 30 MB (there are 8 segments available). Therefore, when one modifies the claim rules, set the size to 240 MB and set both other columns to true (even though the array reported values column is not used).

The process to change the claim rules involves removing the existing VAAI rule class, adding it back with the new columns set, and then loading the rule (to be completed on all servers involved in testing). Following this a reboot of the server is needed. The commands to run on the ESXi host as root are the following. They will not return a response.

```
esxcli storage core claimrule remove --rule 65430 --claimrule-class=VAAI

esxcli storage core claimrule add -r 65430 -t vendor -V EMC -M SYMMETRIX -P VMW_VAAIP_SYMM -c VAAI -a -s -m 240

esxcli storage core claimrule load --claimrule-class=VAAI
```

To verify the changes are set before reboot, list the claim rules as in Figure 31 below:

```
esxcli storage core claimrule list --claimrule-class=VAAI
```

![Figure 31. Updated VAAI claim rule for XCOPY](image)

Note however that the changes will not take effect until a reboot of the server. Once the reboot is complete, re-run the command to ensure the changes appear. Dell EMC always recommends using the maximum value of 240 MB. Using the maximum ensures that if possible, a 240 MB extent will be used.

It is important to remember that the new claim rule does not impact how VAAI functionality works. For instance, the following still hold true:

- It will revert to software copy when it cannot use XCOPY

17 There is a process by which this can be done with the server running which involves unmounting datastores and detaching devices; however, it is not recommended as testing has shown it to be inconsistent.
- It can still be enabled/disabled through the GUI or CLI
- It will use the `DataMover/MaxHWTTransferSize` when the claim rules are not changed or a non-VMAX array is being used
- The maximum value is just that, a maximum. That is the largest extent VMware can send but does not guarantee all extents will be that size.

In the event it is desired to return to the former functionality, simply remove the rule, and add back the claimrule without turning on any settings:

```
esxcli storage core claimrule remove --rule 65430 --claimrule-class=VAAI

esxcli storage core claimrule add -r 65430 -t vendor -V EMC -M SYMMETRIX -P VMW_VAAIP_SYMM -c VAAI

esxcli storage core claimrule load --claimrule-class=VAAI
```

A reboot is again required.

**vSphere 6.7**

Starting in vSphere 6.7, VMware has begun the process of moving away from the custom vendor VAAI plug-ins (VMW_VAAIP_SYMM) enumerated in the previous section. To that end, a new generic plug-in, VMW_VAAIP_T10, is delivered with vSphere 6.7. This generic plug-in works the same way the custom plug-in does. The idea is to eventually deprecate all vendor custom plug-ins. In this release it is important because VMware is extending the XCOPY claim rules from VMAX to any other storage vendor who wishes to support them. Since Dell EMC is the only vendor with this legacy capability, the current implementation enumerated above using the custom plug-in is still supported; however, for new servers which do not already have the claim rules setup for VMAX, Dell EMC recommends using the new generic plug-in.

The steps are similar to the custom plug-in and are as follows:

First, the existing custom vendor rule must be removed. Because VMware suggests using claim rule number 914, remove both the Filter and VAAI classes. This is different than what was done for the custom plug-in as the Filter class did not need to be removed. Note that if an attempt is made to add claim rule 914 before 65430 is removed, VMware will error and indicate 914 is a duplicate of 65430.

```
esxcli storage core claimrule remove --rule 65430 --claimrule-class=Filter

esxcli storage core claimrule remove --rule 65430 --claimrule-class=VAAI
```

Now add the new filter and rule.

```
esxcli storage core claimrule add -r 914 -t vendor -V EMC -M SYMMETRIX -P VAAI_FILTER -c Filter

esxcli storage core claimrule add -r 914 -t vendor -V EMC -M SYMMETRIX -P VMW_VAAIP_T10 -c VAAI -a -s -m 240
```
Reboot the ESXi host for the changes to take effect.

For Storage vMotion operations, VMware will use a maximum of 64 MB for the extent size. This is a VMware restriction and has nothing to do with the array. No change to the claim rules is required. Remember if VMware can use an extent size up to 240 MB it will, if not it will use something smaller. In the case of Storage vMotion it won’t exceed 64 MB.

Thin vmdks

One area where the increased extent size has made no difference in the past is with thin vmdks. As the section Caveats for using hardware-accelerated Full Copy explains, VMware only uses 1 MB extents when copying thin vmdks no matter the value of the extent size. This holds true for both vSphere 4.1 and 5.x. In vSphere 6, however, VMware makes an attempt to consolidate extents and therefore when cloning will use the largest extent it can consolidate for each copy IO (software or hardware). This new behavior has resulted in two benefits on the VMAX. The first is the obvious one that any task requiring XCOPY on thin vmdks will be faster than on previous vSphere versions. The second benefit is somewhat unexpected and that is a clone of a thin vmdk now behaves like a thick vmdk in terms of further cloning. In other words if one clones a thin vmdk VM and then uses that clone as a template for further clones, those further clones will be created at a speed almost equal to a thick vmdk VM clone. This is the case whether that initial clone is created with or without XCOPY. The operation is essentially a defragmentation of the thin vmdk. It is critical, therefore, if a thin vmdk VM is going to be a template for other VMs, that rather than converting the VM to template it is cloned to a template. This will ensure all additional deployments from the template will benefit from the consolidation of extents.

Claim rule results

The following graph, Figure 32, demonstrates the effectiveness of the new vSphere 6 claim rule for XCOPY when cloning between datastores. Note in particular the clone of the clone for the thin vmdk (light green) as explained in the previous paragraph.
Figure 32. XCOPY performance using vSphere 6 claim rules with VMAX

Figure 33 displays comparable results for vSphere 6.7 on PowerMax using claim rules with the new VMware plugin VMW_VAAIP_T10. For a single 500 GB VM clone across two datastores it takes about 17 seconds, which is double the 8 seconds for 250 GB in Figure 32. The use of claim rules is essential on the VMAX and PowerMax to achieve the best performance of Full Copy.
Finally, in Figure 34, are results from a Storage vMotion of the same VM in Figure 33. Note that the copy times are greater than that for the clones. Recall that for Storage vMotion the maximum extent size is 64 MB not 240 MB. Additionally, VMware must maintain consistency during a Storage vMotion, unlike a clone. VMware therefore must do some preparation work at the beginning and end of the job, including marking a point in time so that it can keep track of changes made during the move. Once the bulk of the data is transferred, it then must go back and make requests for all the changed data and may have to repeat this process until it can apply a logical pause to complete the task. These factors result in a longer time than a clone between 2 datastores in the graph above.
SRDF and XCOPY
As previously mentioned previously, XCOPY is implemented asynchronously on the VMAX. Unfortunately, this implementation can cause a potential issue for customers when XCOPY is used in conjunction with SRDF target devices. On the VMAX running the Enginuity operating system, if the target device of an XCOPY operation is an SRDF/S/A device in a consistency group, the group can be rendered into a “sync in progress” mode until the copy completes on the backend of the VMAX. If this is undesirable state, customers are advised to disable XCOPY through the GUI or CLI while cloning to these devices. This will ensure VMware uses host software copy which is synchronous. Alternatively, at Enginuity level 5876.268.174, XCOPY can be disabled on the VMAX for all SRDF devices. This setting will not impact other XCOPY activities.

By default, on the VMAX3, XCOPY is disabled for all SRDF devices so no user intervention is required. Beginning with HYPERMAX OS version 5977 2015 Q3 SR, Dell EMC implements synchronous XCOPY for all target SRDF devices.\(^\text{18}\) The synchronous process ensures that a

\(^{18}\) This change is automatically applied during upgrade to this SR. If circumstances require, it can be changed by Dell EMC.
consistency group will not enter a “sync in progress” state. The two main reasons Dell EMC implemented the synchronous copy are:

1. Avoid any consistency issues with SRDF devices
2. Offload the copy process from the host to the array, thus saving CPU, memory, and bandwidth.

The performance of the synchronous implementation is, by its nature, more akin to VMware’s software copy than Dell EMC’s asynchronous implementation. As such, while Dell EMC synchronous copy will generally outpace VMware’s host copy, though not always, the improvement will not mirror those for asynchronous copy. It is, however, more desirable to offload the copy to the array to free the host and network resources for more important activities. If the time to complete an XCOPY task is more critical than the resources saved on the host, XCOPY can be disabled for SRDF devices on the array by Dell EMC. For more detail on XCOPY performance considerations, please see Dell EMC KB 533648.

eNAS and VAAI

On the VMAX3 starting with the 5977 Q4 release, Dell EMC offers Embedded NAS (eNAS) guest OS (GOS). VMAX3/VMAX All Flash/PowerMax with eNAS extends the value of the VMAX to file storage by enabling customers to leverage vital Tier 1 features including SLO-based provisioning, Host I/O Limits, and FAST technologies for both block and file storage. eNAS enables virtual instances of VNX Software Data Movers and Control Stations to leverage a single platform creating a unified array. The unified solution eliminates gateway complexity by leveraging standard VMAX3/VMAX All Flash/PowerMax hardware and a factory pre-configured eNAS solution.

Because eNAS is based on the VNX software, file systems configured on the VMAX support VAAI. The feature in particular that NAS can take advantage of is NFS Clone Offload, though other features include extended stats, space reservations, and snap of a snap. In essence the NFS clone offload works much the same way as XCOPY as it offloads ESXi clone operations to the VNX Data Mover. The implementation of VAAI on VNX for NAS, however, is a manual process and is not enabled by default like block. It requires the installation of a plug-in on the ESXi host.

To install the plug-in, download the NAS plug-in from Dell EMC support - EMCNasPlugin-2.0-4.zip. The plug-in is delivered as a VMware Installation Bundle (vib). The plug-in can be installed through VMware vCenter Update Manager or through the CLI as demonstrated in Figure 35.
Once installed, the vSphere Client will show that VAAI is supported on the NFS datastores as in Figure 36.

Extended stats

As mentioned, one of the other VAAI integrations for NFS is extended stats. Using vmkfstools the user can display the disk utilization for virtual machine disks configured on NFS datastores. The `extendedstat` argument provides disk details for the virtual disks. The command reports, in bytes, virtual disk size, used space, and unshared space. An example is shown in Figure 37.
Nested clones

Another VAAI capability on NFS is the ability to create a thin-clone virtual machine from an existing thin-clone virtual machine. This functionality is referred to as nested clones. The functionality uses the snapshot architecture to instantaneously create lightweight virtual machine clones. VMware products such as View Composer and vCloud Director use View Composer Array Integration (VCAI) to initiate virtual machine clones using the VNX Data Mover API for nested snapshots. The clone operations are off-loaded to the VNX Data Mover. To take advantage of this feature, enable the nested clone support property when you create the file system as highlighted in Figure 38. It cannot be changed after the file system is created.
Hardware-accelerated Full Copy

The primary use cases that show the benefit of hardware-accelerated Full Copy are related to deploying virtual machines – whether from a template or executing a hot or cold clone. With Full Copy the creation of any of these virtual machines will be offloaded to the array. In addition to deploying new virtual machines, Full Copy is also utilized by Storage vMotion operations, significantly reducing the time to move a virtual machine to a new datastore.

Following are several use cases for Full Copy concerned with the deployment of virtual machines – some from a template and others from cloning – and Storage vMotion. Each use case test is run on thin devices with hardware-accelerated Full Copy disabled and enabled. For the Full Copy enabled results both the 4 MB and 16 MB maximum copy sizes are displayed, as well as the results for VMAX and VMAX3/VMAX All Flash where possible.19

The benefits of using a 16 MB copy size over the default of 4 MB are readily apparent in the use cases, as is the superiority of the VMAX3/VMAX All Flash platform when compared to the previous generation.

In order to distinguish the VMAX platform from the VMAX3/VMAX All Flash platform in the graphs, the abbreviations V2 and V3 are used. Also, the terms Full Copy and XCOPY will be used interchangeably.

Use case configuration

In general, the Full Copy use cases were conducted using the same virtual machine, or a clone of that virtual machine converted to a template. This virtual machine was created using the vSphere Client, taking all standard defaults and with the following characteristics:

- 40 GB virtual disk
- Windows Server 2008 R2 operating system (no VMware Tools)20

The virtual machine was then filled with data equal to 25 GB of the 40 GB. This configuration might be thought of as a worst-case scenario for customers since most virtual machines that are used for cloning, even with the OS and all applications deployed on it, do not approach 25 GB of actual data. Remember that the default configuration of a virtual machine uses a zeroedthick virtual disk. This type of disk, though reserving the 40 GB of space on the VMFS, will not actually write to disk until necessary. This is distinct from a fault-tolerant virtual machine, which must have an eagerzeroedthick (EZT) virtual disk, a disk that is zeroed out entirely upon creation. Since only a small portion of a 40 GB virtual machine will typically contain data, the time to clone a VM in a customer’s environment with Full Copy will invariably take less

19 As it was not possible to recreate the testing environment used for active clones (Figure 26), VMAX3 results are not included; though it is a reasonable assumption to conclude given the other testing that the VMAX3 numbers would be about ½ the 16 MB VMAX results for a similar extent size.
20 If using VMware Tools with Windows 2008 R2, there is a limitation wherein a hot clone will not use Full Copy because of VSS application quiescing. This can be disabled through a configuration parameter. Please see VMware KB articles 1031298 and 1028881 for more information.
time than the results presented in this study. To fully test the functionality and performance, however, 25 GB of data was used.

When creating non-fault-tolerant virtual machines, the cloning times are directly related to how much data is in the virtual machine, not the size of the virtual disk. This is true whether performing a software copy (Full Copy disabled), or a hardware-accelerated Full Copy. From the standpoint of cloning, a zeroed-thick 20 GB VM that has 5 GB of data will take approximately the same amount of time to clone as a 100 GB VM with 5 GB of data.

All results presented in graphs of Full Copy functionality are dependent upon the lab environment under which they were generated. While the majority of the time hardware acceleration will outperform a software copy, there are many factors that can impact how fast both software clones and Full Copy clones are created. For software clones the amount of CPU and memory on the ESXi server as well as the network will play a role. For Full Copy the number of engines and directors and other hardware components on the VMAX will impact the cloning time. The VMAX also intelligently balances workloads to ensure the highest priority to mission critical tasks. In both cases, the existing load on the environment will most certainly make a difference. Therefore, results will vary.

**Use Case 1: Deploying a virtual machine from a template**

The first use case for Full Copy is the deployment of a virtual machine from a template. This is probably the most common type of virtual machine duplication for customers. A customer begins by creating a virtual machine, then installs the operating system and following this, loads the applications. The virtual machine is then customized so that when users are presented with the cloned virtual machine, they are able to enter in their personalized information. When an administrator completes the virtual machine base configuration, it is powered down and then converted to a template.

As using thin striped metadevices is a VMAX best practice for VMware environments, these clones were created on a datastore backed by a thin striped metadevice.\(^{21}\)

The following graph in Figure 39 shows the time difference between clones created using Full Copy and those using software copy.

\(^{21}\) VMAX3 does not have a concept of metadevices.
Use Case 2: Cloning hot and cold virtual machines

The second use case involves creating clones from existing virtual machines, both running (hot) and not running (cold). In addition, a third type of test was run in which a hot clone was sustaining heavy read I/O while it was being cloned. In each instance, utilizing the Full Copy functionality resulted in a significant performance benefit as visible in Figure 40, Figure 41, and Figure 42.
Figure 40. Performance of cold clones using Full Copy
Figure 41. Performance of hot clones using Full Copy
Use Case 3: Creating simultaneous multiple clones

The third use case that was tested was to deploy four clones simultaneously from the same source virtual machine. This particular test can only be conducted against a cold virtual machine.

As seen in Figure 43, the results again demonstrate the benefit of offloading as compared to software copying.
Use Case 4: Storage vMotion

The final use case is one that demonstrates a great benefit for customers who require datastore relocation of their virtual machine, but at the same time desire to reduce the impact to their live applications running on that virtual machine. This use case then is for Storage vMotion. With Full Copy enabled, the process of moving a virtual machine from one datastore to another datastore is offloaded. As mentioned previously, software copying requires CPU, memory, and network bandwidth. The resources it takes to software copy, therefore, might negatively impact the applications running on that virtual machine that is being moved. By utilizing Full Copy this is avoided and additionally as seen in Figure 44, Full Copy is far quicker in moving that virtual machine.
Server resources – impact to CPU and memory

While the relative time benefit of using Full Copy is apparent in the presented use cases, what of the CPU and memory utilization on the ESXi host? In this particular test environment and in these particular use cases, the CPU and memory utilization of the ESXi host did not differ significantly between performing a software clone or a Full Copy clone. That is not to say, however, this will hold true of all environments. The ESXi host used in this testing was not constrained by CPU or memory resources in any way as they were both plentiful; and the ESXi host was not under any other workload than the testing. In a customer environment where resources may be limited and workloads on the ESXi host many and varied, the impact of running a software clone instead of a Full Copy clone may be more significant.
Caveats for using hardware-accelerated Full Copy

The following are some general caveats that Dell EMC provides when using this feature:

- VMware publishes a KB article (1021976) which details when Full Copy will not be issued. Such cases include VMs that have snapshots or cloning or moving VMs between datastores with different block sizes, among others.

- As can be seen from the graphs, utilizing the 16 MB copy size improves performance by factors over the default of 4 MB. Therefore, if the VMware environment is only utilizing VMAX or VMAX and VNX storage, adjust the parameter accordingly as detailed in this paper. If using vSphere 6, follow the process in this paper to increase the extent size to 240 MB.

- One caveat to the extent size change is that the virtual thin disk format (vmdk) is not impacted by the copy size in vSphere 4.1-5.x. Thin disks will always copy in the extent size of the datastore block size, regardless of the parameter setting. For VMFS3 and VMFS5, the default is 1 MB. Therefore, it will always take longer to clone/move a thin disk than a thick disk of equal size (actual data size) with Full Copy. This is not the case with vSphere 6.

- Limit the number of simultaneous clones using Full Copy to three or four. This is not a strict limitation, but Dell EMC believes this will ensure the best performance when offloading the copy process.

- A VMAX metadevice that has SAN Copy, TimeFinder/Clone, TimeFinder/Snap, TimeFinder SnapVX or ChangeTracker sessions and certain RecoverPoint sessions will not support hardware-accelerated Full Copy. Any cloning or Storage vMotion operation run on datastores backed by these volumes will automatically be diverted to the default VMware software copy. Note that the vSphere Client has no knowledge of these sessions and as such the “Hardware Accelerated” column in the vSphere Client will still indicate “Supported” for these devices or datastores.

- Full Copy is not supported for use with Open Replicator. VMware will revert to software copy in these cases.

- Full Copy is not supported for use with Federated Live Migration (FLM) target devices.

- Although SRDF is supported with Full Copy, certain RDF operations, such as an RDF failover, will be blocked until the VMAX has completed copying the data from a clone or Storage vMotion.

- SRDF/Star is not supported with Full Copy if the device is a metadevice.

- Full Copy will not be used if there is a metadevice reconfiguration taking place on the device backing the source or target datastore. VMware will revert to traditional

---

22 Beginning with Enginuity 5876.159.102, Full Copy (XCOPY) can be disabled at the system level if the caveats are particularly problematic for a customer. A special E Pack is required for any Enginuity 5875 release and any 5876 release prior to 159.102. If this change is required, please contact EMC Customer Support as there is no capability for customers to disable XCOPY even if at the correct Enginuity version.
writes in these cases. Conversely if a Full Copy was recently executed and a metadevice reconfiguration is attempted on the source or target metadevice backing the datastore, it will fail until the background copy is complete.

- When the available capacity of a Storage Resource Pool (SRP) reaches the Reserved Capacity value, active or new Full Copy requests can take a long time to complete and may cause VMware tasks to timeout. For workarounds and resolutions please see Dell EMC KB article 503348.

- Full Copy cannot be used between devices that are presented to a host using different initiators. For example, take the following scenario:
  - A host has four initiators
  - The user creates two initiator groups, each with two initiators
  - The user creates two storage groups and places the source device in one, the target device in the other
  - The user creates a single port group
  - The user creates two masking views, one with the source device storage group and one of the initiator groups, and the other masking view with the other initiator group and the storage group with the target device.
  - The user attempts a Storage vMotion of a VM on the source device to the target device. Full Copy is rejected, and VMware reverts to software copy.

**SRDF/Metro specific**

The following are caveats for SRDF/Metro when using Full Copy. In SRDF/Metro configurations the use of Full Copy does depend on whether the site is the one supplying the external WWN identity.

- Full Copy will not be used between a non-SRDF/Metro device and an SRDF/Metro device when the device WWN is not the same as the external device WWN. Typically, but not always, this means the non-biased site (recall even when using witness, there is a bias site). In such cases Full Copy is only supported when operations are between SRDF/Metro devices or within a single SRDF/Metro device; otherwise software copy is used.

- As Full Copy is a synchronous process on SRDF/Metro devices, which ensures consistency, performance will be closer to software copy than asynchronous copy.

- While an SRDF/Metro pair is in a suspended state, Full Copy reverts to asynchronous copy for the target R1. It is important to remember, however, that Full Copy is still bound by the restriction that the copy must take place on the same array. For example, assume SRDF/Metro pair AA, BB is on array 001, 002. In this configuration device AA is the R1 on 001 and its WWN is the external identity for device BB, the R2 on 002. If the pair is suspended and the bias is switched such that BB becomes the R1, the external identity still remains that of AA from array 001 (i.e. it appears as a device from 001). The device, however, is presented
from array 002 and therefore Full Copy will only be used in operations within the device itself or between devices on array 002.

**Compression/Deduplication specific**

The following are caveats when using Full Copy with devices in storage groups with compression or compression/deduplication enabled. Note that deduplication is only available on the PowerMax platform and only in conjunction with compression. It is not possible to enable one without the other. As such, references to compression below also include the PowerMax.

- When Full Copy is used on a device in a storage group with compression enabled, or between storage groups with compression enabled, Full Copy will uncompress the data during the copy and then re-compress on the target.
- When Full Copy is used on a device in a storage group with compression enabled, to a storage group without compression enabled, Full Copy will uncompress the data during the copy and leave the data uncompressed on the target.
- When Full Copy is used on a device in a storage group without compression enabled to a storage group with compression enabled, the data will remain uncompressed on the target and be subject to the normal compression algorithms.
- As Full Copy is a background process, deduplication of data, if any, may be delayed until after all tracks have been copied. Full clone copies have been shown to deduplicate at close to 100% in enabled storage groups.

**Hardware-accelerated Block Zero**

Hardware-accelerated Block Zero provides benefits and performance increases in a variety of use cases. This paper will cover the two most commonly encountered scenarios. The first scenario discussed will be concerned with deploying fully allocated virtual machines (virtual machines using the “eagerzeroedthick” virtual disk allocation mechanism) on both VMAX and VMAX3/VMAX All Flash. The second use case discusses the performance gains achieved using Block Zero when performing I/O in a virtual machine with virtual disks using the zeroedthick allocation format on the VMAX.

**Use Case 1: Deploying fully allocated virtual machines**

In certain situations, virtual disks are deployed using the “eagerzeroedthick” allocation mechanism to fully zero out the disk at creation. A VMware feature that requires EZT disks is VMware Fault Tolerance. Fault Tolerance requires that all virtual disks in use by protected virtual machines use this allocation mechanism. In other cases, virtual disks are created using the “thin” or “zeroedthick” allocations.

---

23 Compression on the VMAX All Flash is available beginning with release 5977 2016 Q3 SR. Deduplication is only available on the PowerMax platform.
mechanisms where space is not fully allocated on creation of the virtual disk. Both of
these mechanisms will not zero out the space until the guest OS writes data to a
previously unallocated block. This behavior inherently will cause a performance drop
when allocating new space as the kernel must first write zeros to initialize the new
space before the virtual machine can write actual data. Therefore, the
“eagerzeroedthick” allocation mechanism is used to avoid performance degradations
caused by the on-the-fly zeroing of “thin” or “zeroedthick” virtual disks.

Since “eagerzeroedthick” virtual machines are entirely zeroed at the initial creation, it
can take a great deal of time to write these zeros, especially in virtual machines with
large virtual disks. Furthermore, this creation operation consumes SAN bandwidth
during execution. With the introduction of Block Zero, the zeroing is offloaded to the
array, which saves not only on SAN bandwidth but also takes advantage of the
increased processing power inherent on the VMAX. It therefore writes these zeros
faster and more efficiently.

On the VMAX if thin devices are used in conjunction with Block Zero, the zeros are
discarded by the VMAX and thin pool capacity is reserved for non-zero data. As a
result no zeros are actually written by the VMAX; rather it just sets a flag called Never
Written By Host (NWBH) which reserves the space. As previously explained, on the
VMAX3/VMAX All Flash/PowerMax no space is actually reserved.

As the VMAX3/VMAX All Flash/PowerMax does not actually reserve space, it seems
logical to conclude that there is little difference between using an eagerzeroedthick
and a zeroedthick virtual disk on that platform. While this is essentially true from a
storage performance perspective, it is important to remember that if VMware or an
application requires the use of an eagerzeroedthick virtual disk (e.g. Fault Tolerant
VM, Oracle RAC), that disk type must be selected when creating the virtual machine.

In this use case, new virtual disks of varying sizes (10 GB, 20 GB, 40 GB, 60 GB, 100
GB, and 200 GB) were deployed using the “eagerzeroedthick” allocation mechanism
on thin devices (striped metadevices on VMAX24) with hardware-accelerated Block
Zero disabled and enabled. As shown by the graph in Figure 45, the noted
improvements are significant. Although in viewing the graph it may appear that larger
disk sizes bring greater improvement, the benefit is actually very consistent within
each VMAX platform (abbreviated in the graph as follows: VMAX – V2, VMAX3/VMAX
All Flash – V3). The performance benefit of the VMAX3/VMAX All Flash over the VMAX
is also apparent both with and without Block Zero enabled.

---
24 VMAX3/VMAX All Flash/PowerMax do not have a concept of metadevices.
In addition to time savings, there is a substantial difference in throughput during the creation of the virtual disks when Block Zero is off and on. Figure 46 shows the ESXi performance graph of the write rate in KB per second (throughput) of the target VMAX3/VMAX All Flash device from the ESXi server creating the virtual disk. A dramatic difference can be noted between when Block Zero is off and on. A virtual disk is created with hardware acceleration off and takes 2 minutes and has a write rate exceeding 150,000 KB/s. After the virtual disk creation completes, hardware-accelerated Block Zero is enabled and a second identical virtual disk is created on the same target VMAX3/VMAX All Flash device. The throughput required to deploy this is so low that it is unseen on the same scale as the first virtual disk creation. The throughput spikes at around 587 KB/s for around 2 seconds — a 250x decrease in required throughput to create the virtual disk!

Figure 45. Fully allocated virtual disk deployment times using Block Zero
Use Case 2: Benefits of Block Zero when using zeroedthick virtual disks

By default, in ESXi 4.x - 6, new virtual disks are created using the “zeroedthick” allocation mechanism. This is also the recommended disk format for use with VMAX Virtual Provisioning to improve storage efficiencies by not writing zeros on creation. In this allocation scheme, the storage required for the virtual disks is reserved in the datastore but the VMware kernel does not initialize all the blocks with zeros. The blocks are initialized with zeros by the ESXi kernel in response to I/O activities to previously uninitialized blocks by the guest operating system. Consequently, as discussed in the previous use case, there is overhead when writing to unallocated regions of the virtual disk as the ESXi kernel first must write zeros to the previously unallocated space before the guest can complete any new write operations. Prior to the VAAI primitives, to avoid this overhead, “eagerzeroedthick” virtual disks were used to ensure optimal performance. Unfortunately, especially in the case of Virtual Provisioning, “eagerzeroedthick” virtual disks wasted inordinate amounts of space in the thin pool due to the zeros written at creation. A decision therefore needed to be made between consuming more capacity with “eagerzeroedthick” virtual disks and accepting the inherent performance overhead associated with “zeroedthick” virtual disks. With the advent of Block Zero, however, that performance overhead is negated as the zeros are no longer written to initialize blocks before the guest OS writes to them.
In this use case, the benefits of having hardware-accelerated Block Zero enabled will be explored when writing to unallocated regions of a “zeroed-thick” virtual disk using a “real-world” testing configuration. In this test, the tool IOMETER was used to demonstrate the performance impact of using Block Zero. The testing environment consisted of a VM that was configured in the same manner as the one used in the Full Copy use cases, created on a thin striped metadevice datastore. For each test a 10 GB virtual disk was added to the VM and put online but not formatted. A “real-world” performance test was executed on the 10 GB virtual disk in IOMETER which had the following characteristics:

- 8 KB transfer request size
- 40% sequential and 60% random workload
- 35% write and 65% read distribution
- 5-minute test cycle

The IOMETER test was executed with Block Zero disabled and enabled, using a different 10 GB virtual disk for each test, though each was located on the same thin striped metadevice datastore. By displacing the process of the zero initialization from the ESXi kernel to the VMAX, it introduces a marked improvement in writing to unallocated virtual disk regions. This performance improvement is depicted graphically in Figure 47, which shows a 30% improvement in both response time and the amount of connections possible when Block Zero is enabled.
In addition, Figure 48 demonstrates a 15% increase in the number of transactions per second accomplished during this test with Block Zero enabled.
Server resources -- impact to CPU and memory

While the relative time benefit and drop of overall throughput of using block zero is readily apparent in the presented use cases, what of the CPU and memory utilization on the ESXi host? In this particular test environment and in these particular use cases, the CPU and memory utilization of the ESXi host did not differ significantly between when Block Zero was enabled or disabled. That is not to say, however, this will hold true of all environments. The ESXi host used in this testing was not constrained by CPU or memory resources in any way as they were both plentiful; and the ESXi host was not under any other workload than the testing. In a customer environment where resources may be limited and workloads on the ESXi host many and varied, the impact of utilizing Block Zero may be more significant.

Caveats for using hardware-accelerated Block Zero

The following are some general caveats that Dell EMC provides when using this feature:
• Block Zero is currently not supported for use with Open Replicator. VMware will revert to traditional writes in these cases.

• Block Zero will not be used if there is a metadevice reconfiguration taking place on the device backing the datastore. VMware will revert to traditional writes in these cases.

• Block Zero commands will take longer to execute on devices in SRDF relationships.

UNMAP

In this paper the VMware use cases for UNMAP revolve around the time it takes to reclaim storage space after the deletion of virtual disks, virtual machines, or the execution of a Storage vMotion. All of these tasks create empty space on the datastore but not in the backing thin pool on the array. What is of particular interest from the array side, though, is how a device’s configuration might impact the time it takes to deallocate the thin pool space. Dell EMC replication technologies such as TimeFinder and SRDF add an extra layer of complexity, so comparing these devices to standard thin devices will provide guidance to the user on how long a reclaim on a datastore might take.

While most of the examples will utilize VMFS 6 and the automatic UNMAP feature, manual unmapping is still supported on VMFS 6 and is still required for VMFS 5, no matter the vSphere version. Therefore, the first use case will be a standard manual UNMAP on a VMFS 6 datastore which has automation disabled.

Manual UNMAP after VM deletion

This example will demonstrate the manual reclamation of a datastore’s storage using the ESXi CLI. The environment for the test consists of:

• A single device (4FD), in a compressed/deduplicated storage group presented to the ESXi hosts.

• 1 TB datastore, NO_AUTO_UNMAP, created on that device.

• 1 Windows VM, NO_AUTO_UNMAP_VM_1, with 600 GB of storage. Almost all of that storage is comprised of files on NTFS. There is minimal free space.

In Figure 49, VMware reports that the VM is occupying 601.42 GB. Unisphere for PowerMax has a similar allocation in Figure 50.

---

25 The UNMAP process is also known as Dead Space Reclamation and for the purposes of this paper the terms reclaim or unmapping should also be considered synonymous with the UNMAP process.
More detail about how PowerMax has allocated the storage is available through SYMCLI. Note in Figure 51 how tracks are in different pools, depending on how they can be compressed. In addition, the allocated tracks are not the same as exclusive tracks since some data in this VM is already available on the array and thus has been deduplicated. So, while the VM would normally consume 600 GB of storage, it actually only needs 421 GB on the PowerMax.
Now once the VM is deleted (or moved), VMware will recognize that the datastore is empty in Figure 52, but as automatic UNMAP is not enabled, the allocation on the array remains as in Figure 51.
At this point space can be reclaimed using a manual UNMAP. One thing to understand about manual reclaim is that VMware cannot do a “precision” UNMAP like automatic reclamation. If auto UNMAP was enabled on this datastore, VMware would only send commands for those LBAs which used to represent the VM. With manual reclamation, VMware must iterate all the segments of the entire datastore, reclaiming what it can. Therefore, the time it takes to reclaim will be dependent both on the size of the device and the amount of storage to reclaim, with the device size being the more important factor in timing.

In the above example, the following script in Figure 53 was run which records the time before and after the UNMAP command. Note we do not recommend changing the reclaim blocks from the default of 200, which is 200 MB reclaimed for each iteration. So to reclaim 421 GB on a 1 TB datastore took 58 seconds.

![Manual UNMAP command](image)

**Figure 53. Manual UNMAP command**

Here is the device allocation after the run in Figure 54.
So basically, all storage (save some datastore metadata or any blocks that could not be reclaimed) has been returned to the SRP and is available for other devices. Note what happens in Figure 55 if the script is run again, even though there is nothing left to reclaim.
Interestingly it also shows that the actual UNMAP process took about 12 seconds. Hence, device size is very important to consider when running a manual UNMAP. Extremely large datastores will take time and impact ongoing IO on the datastore, and therefore it is advisable to execute any manual reclamations during maintenance windows.

How the space is reclaimed with this command, whether through CLI or GUI, is a bit different. With the former implementation of vmkfstools, a temp file(s) was created at the start of the operation and then an UNMAP was issued to all the blocks that were allocated to these temp files. Since the temp file(s) could take up all the free blocks in the volume, any other operation that required a new block allocation would fail. To prevent that failure, VMware permitted the user to provide a percentage of the free blocks to reclaim. The user could then issue the command multiple times to reclaim all of the space.

In ESXi 5.5+, dead space is reclaimed in multiple iterations instead of all at once. A user can now provide the number of blocks (the default is 200) to be reclaimed during each iteration. This specified block count controls the size of each temp file that VMware creates. Since vSphere 5.5+ defaults to 1 MB block datastores, this would mean that if no number is passed, VMware will unmap 200 MB per iteration. VMware still issues UNMAP to all free blocks, even if those blocks have never been written to. VMware will iterate serially through the creation of the temp file as many times as needed to issue UNMAP to all free blocks in the datastore. The benefit now is that the risk of temporarily filling up available space on a datastore due to a large balloon file is essentially zero.

As before, this command uses the UNMAP primitive to inform the array that these blocks in this temporary file can be reclaimed. This enables a correlation between what the array reports as free space on a thin-provisioned datastore and what vSphere reports as free space. Previously, there was a mismatch between the host and the storage regarding the reporting of free space on thin-provisioned datastores.

Unlike the previous unmap methodology with vmkfstools, VMware advises that the new procedure in ESXi 5.5+ can be run at any time, and not relegated to maintenance windows; however, Dell EMC still suggests reclaiming space in off-peak time periods. Dell EMC recommends using VMware’s default block size number (200), though fully supports any value VMware does. Dell EMC has not found a significant difference in the time it takes to unmap by increasing the block size number.

**ESXi 6.x**

Beginning with ESXi 5.5 Patch 3 (build 2143827), VMware changed UNMAP behavior once again. At this code version, when issuing an UNMAP, any time a non-default block value is used that is higher than 1% of the free space in the datastore, VMware will revert to the default size (200). In addition, if the datastore is 75% full or more, it will also revert to the default. To determine the most ideal value to pass to VMware, therefore, calculate the amount of free space in the datastore in MB and multiply it by .01 and round down. Failing to round down may result in a number that exceeds 1% and VMware will revert to the default. Using this methodology is most beneficial when there is a large amount of free space to reclaim as the...
VMAX3/VMAX All Flash/PowerMax are very fast to UNMAP even at the default. Free space can be determined through the vSphere Client or even a PowerCLI script. Figure 56 demonstrates the benefit of using 1% over the default.

**Figure 56. UNMAP in ESXi 5.5 P3+/ESXi 6.x**

<table>
<thead>
<tr>
<th>Amount of Free Space Reclaimed</th>
<th>Default block size (200)</th>
<th>1% free space</th>
</tr>
</thead>
<tbody>
<tr>
<td>500 GB</td>

<td>1000 GB</td>
<td>182</td>
<td>46</td>
</tr>
<tr>
<td>1500 GB</td>
<td>277</td>
<td>66</td>
</tr>
</tbody>
</table>

Note that using 1% has the same scaling as the default, e.g. double the storage reclaimed takes about double the time.

**Using UNMAP with devices over 2 TB in ESXi 5.0 and 5.1**

VMware has a limitation with the UNMAP mechanism prior to ESXi 5.5 that prevents vmkfstools from reclaiming more than 2 TB in a single operation. The reason for the problem appears to be that VMware cannot create a temporary balloon file beyond 2 TB. If an attempt is made to reclaim that amount of space with a single vmkfstools command, ESXi will generate errors, one of which is shown in Figure 57. This command should be cancelled with a CNTRL-C so VMware can properly clean-up any files.
Figure 57. Attempting to UNMAP more than 2 TB

If the space to be reclaimed is greater than 2 TB, simply issue the vmkfstools command with a smaller percentage multiple times to complete the UNMAP as in Figure 58.

Figure 58. UNMAP more than 2 TB with multiple operations

Following now are a few use cases which are primarily based upon the device configuration on the VMAX and how the time to reclaim is impacted by it.

Use case configuration

VMAX (V2)

Each use case test in this section is run on a 500 GB thin striped metadevice which is bound to a Fibre Channel pool of disks. The virtual machines that fill the datastore are all comprised of a single, eagerzeroedthick virtual disk which was created without the use of the Block Zero primitive, forcing all zeros to be written to the array. The datastore is completely filled-up, and then a virtual machine in one of three sizes, 75 GB, 150 GB, or 300 GB is deleted. The \texttt{vmkfstools \textasciitilde y} command is then run using, in most use cases, 99%. Although VMware recommends using a smaller percentage
when reclaiming to prevent out-of-space conditions in the datastore, the best practice would be to run a reclaim during a maintenance window and as such using 99% would not be unwarranted if the datastore and underlying device were idle.

**VMAX3/VMAX All Flash (V3)**

As the V3 does not have metadevices, a single 500 GB device was created using an “Optimal” SLO. In addition, because of architectural changes on the V3, each vmdk of the VM was filled-up manually rather than using eagerzeroedthick without the Block Zero primitive. The V3 was also tested only on ESXi 5.5 and 6 which demonstrated similar results.

The results in the use cases are only meant as examples of reclaim operations and are dependent upon the lab environment under which they were generated. Although every effort is made to mimic the typical activity in a customer environment it is important to understand that results will vary. Note that although only the results from the pre-ESXi 5.5 vmkfstools command is shown for all but the first use case, the `esxcli storage vmfs unmap` command in vSphere 5 and 6 demonstrates similar scaled results, though on the V2 the new process takes longer to complete due to the asynchronous nature of VMware’s implementation. The V3 architecture means its performance exceeds both UNMAP methodologies on the V2.

**Use Case 1: UNMAP baseline on a standard thin device**

The first use case is to run the reclaim operation on the device without any other relationships or outside environmental impacts. This will be considered the baseline and the results for the ESXi 5.1 will be used for the purpose of comparison in the other tests. The results in Figure 59 demonstrate that the time it takes to reclaim space increases fairly consistently as the amount of space increases. This is true for the VMAX (V2) and the VMAX3/VMAX All Flash (V3) platform. For instance, to reclaim 150 GB at ESXi 5.1 takes 100 seconds while to reclaim 300 GB at takes 202 seconds, almost exactly double the time for double the size. The results for the other tests are similar.
Use Case 2: UNMAP with SRDF devices

The second use case is for devices that are in an SRDF relationship, either synchronous or asynchronous. The results are presented together in the same graph. Only the results from a 99% space reclaim are shown in Figure 60.

Figure 59. UNMAP on thin devices
Figure 60. UNMAP on SRDF devices

As might be expected, since SRDF/A batches changes and sends them over asynchronously, the time to UNMAP takes less time on SRDF/A devices than on the synchronous SRDF/S devices; however, both experience significant impact from the process in comparison to the baseline. This again points to the importance of running UNMAP during maintenance windows. Note also that unlike the baseline tests, there is more variability in the results for the different amounts of space reclaimed. This will also hold true for the next use case.

Use Case 3: UNMAP with TimeFinder/Clone device

In customer VMAX environments it is not uncommon for devices used in production VMware environments to have TimeFinder/Clone relationships. Therefore, a test was run on this type of device. In general, as Figure 61 shows, the time it takes to reclaim space on a device with a TimeFinder/Clone relationship is a little more than double that of a device without the relationship.
Use Case 4: UNMAP with device under high FA load

The final use case utilizes the baseline thin device but loads the front-end ports to see if there is any noticeable impact to the reclaim process. The FAs were loaded to about 50% as seen in Figure 62.
While the FAs remain loaded, the reclaim process was run. The results in Figure 63 demonstrate a relatively minor impact, which nevertheless one could expect to become more significant if the FA load continued to rise.

Figure 62. Unisphere for VMAX showing FA load
Figure 63. UNMAP on device while under FA load

Caveats for using UNMAP
The following are some general caveats that Dell EMC provides when using this feature:

- UNMAP is an online activity and can be run on datastores with active VMs, however manually reclaiming large amounts of storage at one time can impact device and thus VM performance. Therefore, Dell EMC recommends running any manual reclaim either during maintenance windows or during a time of lower business activity.

- When an UNMAP process is run on a device (datastore or GuestOS), the PowerMax prioritizes releasing the storage on the device over the thin pool. This means it is possible that even if the device reports the space as reclaimed, the array may still be freeing space from the thin pool and SRP. This is as designed since it ensures that control of the device in VMware is returned to the user as soon as possible so
they can continue to work. Normally the asynchronous nature of UNMAP is not an issue, however if the thin pool or SRP as a whole is approaching capacity, it may be necessary to monitor the release of storage in the SRP before re-using the space the device now shows as free. To avoid this problem in an environment where the SRP is approaching capacity, Dell EMC does not advise performing many large, manual UNMAP procedures of datastores at one time. In addition, if using VMFS6, automated UNMAP is strongly recommended as the freeing of extents occurs in smaller amounts, and only as needed.

- Not supported on devices in use by Open Replicator for VMAX (ORS)
- Not supported with devices in use by RecoverPoint
- Not supported for encapsulated FTS devices
- Can be partially blocked by thin devices that have persistent allocations. The VMAX accepts the UNMAP command but respects persistent allocations. If the specified UNMAP range has persistent and non-persistent allocations, the VMAX will de-allocate the non-persistent allocations and leave the persistent allocations.
- Not supported with TimeFinder/Snap targets
- Not supported with devices currently involved in duplicate write sessions (this is a temporary state; these sessions are used during meta reconfiguration and expansion)
- Not supported with TimeFinder/VP Snap targets

UNMAP to a thin SRDF device is accepted and supported on the R1 and is propagated to its remote replicas (R21, R2) if the links are active and the remote boxes are also running a minimum of Enginuity 5876.159.102.

In addition to these caveats, here are a few particular situations to be aware of when using UNMAP:

- Although there are no support issues using the Full Copy primitive with the UNMAP primitive, if there is an active XCOPY session from a source to target device and a reclaim is run on the source device, operational limits may be reached which will throttle the UNMAP process, increasing the time to complete both the UNMAP and the XCOPY process. Such a situation could occur if a Storage vMotion is run and then a reclaim is issued immediately afterwards on the source device now that the space is released. Note this can be true for both manual and automatic UNMAP.

- Attempting to reclaim a large amount of free space in ESXi 5.1 may result in the memory heap error shown in Figure 64:
Figure 64. Experiencing a memory heap error during an UNMAP operation

In order to resolve this follow VMware KB article 1004424: An ESXi/ESX host reports VMFS heap warnings when hosting virtual machines that collectively use 4 TB or 20 TB of virtual disk storage.

- If you must cancel an UNMAP job (vmkfstools --y) after it has started, only use CNTRL-C which will signal VMware to clean-up the temporary file it creates during the reclaim process. If the UNMAP job is killed or cancelled in any other manner, the hidden file will not be removed. More importantly, however, VMware will keep the datastore locked even if the file is manually removed and will not release the space occupied by that hidden file. The only resolution to this is to reboot the ESXi host.

**Monitoring VAAI operations with ESXTOP**

The VMware ESXTOP tool provides a real-time view (updated every five seconds, by default) of ESXi Server performance details. ESXTOP lists CPU utilization for each physical processor, memory utilization, and disk and network bandwidth/information for each network and disk device available to the ESXi server. These statistics let you monitor the resource utilization for each of your virtual machines and the ESXi kernel. ESXTOP also provides VAAI statistics for each device present to the given ESXi host and allows users to monitor the number of commands being issued (if any) and if there are failures.

To use ESXTOP, login to the console of the ESXi host directly or via SSH.

ESXTOP can either be run in live mode to monitor in real time or batch mode to collect statistics over a period. For the purposes of this paper live mode will be used. For information on batch mode refer to VMware documentation.

ESXTOP is launched by executing the command `esxtop`. ESXTOP defaults to showing CPU information of current running processes. In order to see VAAI information the “disk device” screen must be selected. To change to this screen simply hit the “u” key (no quotation marks) on your keyboard and the screen will automatically change to the “disk device” screen (as seen in Figure 65) which will list the storage devices and their live statistics.
For the purposes of VAAI monitoring, most of the statistics shown by default are unnecessary so they can be removed to make the display more manageable. To edit what is shown press the “f” key on the keyboard and this will show the “Current Field Order” screen. In this screen the user can re-order or add/remove statistics. For VAAI monitoring only the columns “Device Name”, “VAAI Stats” and the “VAAI Latency Stats” are required. Statistics can be added or removed by locating their assigned letter to the left of the field name and toggling the asterisk next to it by typing the associated letter. The presence of an asterisk means the column/field is enabled and will appear when the user navigates back to the “Disk Device” screen. In this example neither of the VAAI fields are enabled so they were enabled by pressing their respective assigned letters, “o” and “p”. Four other default but unnecessary fields for VAAI purposes were disabled by toggling their asterisk by typing their respective lower-case letters. These selections can be seen in Figure 66.
Figure 66. Adding VAAI statistics

Once the statistics desired have been added and others removed, return to the original screen by pressing return or enter on the keyboard. Figure 67 displays the VAAI statistic columns while Table 2 defines them.

</tr>
</tbody>
</table>

It is important to note that with the “VAAISTATS” counters some are running totals and some are averages. The throughputs are averages for the last interval (default is five seconds and can be changed by typing “s” and typing another time in seconds and pressing enter) so if a VAAI command has not been run in the last interval the number will be zero. All of the other commands are running totals since the last reboot.

A common use case for using ESXTOP VAAI statistics is to find out if a XCOPY session has been reverted to software copy due to an exhaustion of resources for queued data at a VMAX device. By watching the CLONE_F column for the given device in a XCOPY session a user can watch for failed XCOPY commands to appear²⁸. If the CLONE_F number increments and the CLONE_RD/CLONE_WR statistics stop incrementing for that device it is likely the resource ceiling has been breached. If the

²⁷ Note that since UNMAP was introduced in ESX 5.x there are no statistics in ESX 4.x ESXTOP for UNMAP and therefore these columns do not exist.
²⁸ The exact number of expected failures cannot be provided as it can vary depending on the number of logical paths to the device(s), the Path Selection Policy (PSP) and the Multi-Pathing Plugin (MPP). In general though this number will be low (single digits or low double digits).
CLONE_RD/CLONE_WR stops incrementing and the CLONE_F does not increase this means the entire XCOPY session completed successfully. Figure 68 shows an ESXTOP example of a XCOPY failure. It reports four failed XCOPY operations before aborting XCOPY and reverting to traditional software copy.

Figure 68. ESXTOP XCOPY Statistics

ESXTOP will only show the number of commands sent for XCOPY. It cannot show the user how large the extent size of each command request is. When using claim rules with vSphere 6.x, therefore, it is a good idea to get a baseline of a VM clone with the default transfer size (4 MB or 16 MB) before adding the claim rule so that it will be easy to determine if the new 240 MB extent size is in use.

In addition to the “VAAISTATS” are the “VAAILATSTATS/cmd” which shows the average latency for the different VAAI commands in milliseconds. Table 3 shows the available statistics.

Table 3. ESXTOP VAAI Latency Statistics

<table>
<thead>
<tr>
<th>Statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>CAVG/suc</td>
<td>The average latency of successful XCOPY commands in milliseconds.</td>

<tr>
<td>ZAVG/f</td>
<td>The average latency of failed WRITE SAME commands in milliseconds.</td>
</tr>
</tbody>
</table>

If VAAI operations are taking a long time or failures are reported, the VAAI latency statistics (Figure 69) are a valuable mechanism to help troubleshoot the problem. If for instance XCOPY sessions are running slower than normal but there are no rejections reported in the CLONE_F column, abnormally high latency could be a factor. If the latencies are much higher than normal this could indicates resource contention on the SAN fabric or the frontend of the VMAX array. At that point the System Administrator would need to troubleshoot the problem through Unisphere for VMAX/PowerMax or other SAN fabric tools.

Figure 69. ESXTOP VAAI latency statistics

**Monitoring VAAI with NFS**

Unfortunately, ESXTOP will not show the user VAAI NFS activity. It is necessary to tail the vpxa log file, searching for “Vstorage” entries. Figure 70 has a sample output of an environment during a clone.

---

<sup>29</sup> There is a display issue with the 5.x version of ESXTOP where ZAVG/suc is actually displayed as AVG/suc. This is fixed in vSphere 6.
Monitoring VAAI operations on Dell EMC PowerMax

Beginning with PowerMaxOS 5978.xxx, there are new VAAI statistics available in Unisphere to monitor VAAI commands.

- VAAI Total Command Count
- VAAI Total Time
- VAAI Unmap Command Count
- VAAI Unmap KB
- VAAI Unmap MB
- VAAI Write Same Command Count
- VAAI Write Same KB
- VAAI Write Same MB
- VAAI XCopy Command Count
- VAAI XCopy KB
- VAAI XCopy MB
Conclusion

Utilizing VMware’s Storage API integrations which permit the offloading of specific VMware operations to Dell EMC’s VMAX benefit overall system performance and efficiency. The VMware Storage APIs for Array Integration are: Full Copy, Block Zero, hardware-assisted locking, and Dead Space Reclamation. In supported VMware/VMAX configurations, all these primitives are enabled by default and will be utilized on the VMAX without any user configuration or intervention.4
